# Coccinelle Usage (version 0.2.1)

## March 12, 2010

## 1 Introduction

This document describes the options provided by Coccinelle. The options have an impact on various phases of the semantic patch application process. These are:

- 1. Selecting and parsing the semantic patch.
- 2. Selecting and parsing the C code.
- 3. Application of the semantic patch to the C code.
- 4. Transformation.
- 5. Generation of the result.

One can either initiate the complete process from step 1, or to perform step 1 or step 2 individually. Coccinelle has quite a lot of options. The most common usages are as follows, for a semantic match foo.coci, a C file foo.c, and a directory foodir:

- spatch -parse\_cocci foo.cocci: Check that the semantic patch is syntactically correct.
- spatch -parse\_c foo.c: Check that the C file is syntactically correct. The Coccinelle C parser tries to recover during the parsing process, so if one function does not parse, it will start up again with the next one. Thus, a parse error is often not a cause for concern, unless it occurs in a function that is relevant to the semantic patch.
- spatch -sp\_file foo.cocci foo.c: Apply the semantic patch foo.cocci to the file foo.c and print out any transformations as a diff.
- spatch -sp\_file foo.cocci foo.c -debug: The same as the previous case, but print out some information about the matching process.
- spatch -sp\_file foo.cocci -dir foodir: Apply the semantic patch foo.cocci to all of the C files in the directory foodir.
- spatch -sp\_file foo.cocci -dir foodir -include\_headers: Apply the semantic patch foo.cocci to all of the C files and header files in the directory foodir.

In the rest of this document, the options are annotated as follows:

- • : a basic option, that is most likely of interest to all users.
- $\bullet$ : an option that is frequently used, often for better understanding the effect of a semantic patch.
- $\diamond$ : an option that is likely to be rarely used, but whose effect is still comprehensible to a user.
- An option with no annotation is likely of interest only to developers.

## 2 Selecting and parsing the semantic patch

### 2.1 Standalone options

◆ -parse\_cocci (file) Parse a semantic patch file and print out some information about it.

## 2.2 The semantic patch

• -sp\_file \( \file \), -c \( \file \), -cocci\_file \( \file \) Specify the name of the file containing the semantic patch. The file name should end in .cocci. All three options do the same thing; the last two are deprecated.

## 2.3 Isomorphisms

- -iso, -iso\_file Specify a file containing isomorphisms to be used in place of the standard one. Normally one should use the using construct within a semantic patch to specify isomorphisms to be used in addition to the standard ones.
- ♦ -iso\_limit (int) Limit the depth of application of isomorphisms to the specified integer.
- ♦ -no\_iso\_limit Put no limit on the number of times that isomorphisms can be applied. This is the default.
  - -track\_iso Gather information about isomorphism usage.
  - -profile\_iso Gather information about the time required for isomorphism expansion.

## 2.4 Display options

- ♦ -show\_cocci Show the semantic patch that is being processed before expanding isomorphisms.
- ♦ -show\_SP Show the semantic patch that is being processed after expanding isomorphisms.
- ♦ -show\_ctl\_text Show the representation of the semantic patch in CTL.
- ◆ -ctl\_inline\_let Sometimes let is used to name intermediate terms CTL representation. This option causes the let-bound terms to be inlined at the point of their reference. This option implicitly sets -show\_ctl\_text.
- ♦ -ctl\_show\_mcodekind Show transformation information within the CTL representation of the semantic patch. This option implicitly sets -show\_ctl\_text.
- ♦ -show\_ctl\_tex Create a LaTeX files showing the representation of the semantic patch in CTL.

## 3 Selecting and parsing the C files

## 3.1 Standalone options

- ◆ -parse\_c ⟨file/dir⟩ Parse a .c file or all of the .c files in a directory. This generates information about any parse errors encountered.
- ◆ -parse\_h ⟨file/dir⟩ Parse a .h file or all of the .h files in a directory. This generates information about any parse errors encountered.

- → -parse\_ch \( \file/\dir \)\ Parse a .c or .h file or all of the .c or .h files in a directory. This generates information about any parse errors encountered.
- -control\_flow \(\file\), -control\_flow \(\file\):\(\function\) Print a control-flow graph for all of the functions in a file or for a specific function in a file. This requires dot \((\text{http://www.graphviz.org/})\) and gv.
- ♦ -type\_c ⟨file⟩ Parse a C file and pretty-print a version including type information.
  - -tokens\_c ⟨file⟩ Prints the tokens in a C file.
  - **-parse\_unparse** (file) Parse and then reconstruct a C file.
  - -compare\_c  $\langle \text{file} \rangle$ , -compare\_c\_hardcoded Compares one C file to another, or compare the file tests/compare1.c to the file tests/compare2.c.
  - -test\_cfg\_ifdef \langle file \rangle Do some special processing of #ifdef and display the resulting control-flow graph. This requires dot and gv.
  - -test\_attributes (file), -test\_cpp (file) Test the parsing of cpp code and attributes, respectively.

## 3.2 Selecting C files

An argument that ends in .c is assumed to be a C file to process. Normally, only one C file or one directory is specified. If multiple C files are specified, they are treated in parallel, *i.e.*, the first semantic patch rule is applied to all functions in all files, then the second semantic patch rule is applied to all functions in all files, etc. If a directory is specified then no files may be specified and only the rightmost directory specified is used.

- -include\_headers This option causes header files to be processed independently. This option only makes sense if a directory is specified using -dir.
- -use\_glimpse Use a glimpse index to select the files to which a semantic patch may be relevant. This option requires that a directory is specified. The index may be created using the script coccinelle/scripts/glimpseindex\_cocci.sh. Glimpse is available at http://webglimpse.net/. In conjunction with the option -patch\_cocci this option prints the regular expression that will be passed to glimpse.
- ♦ -dir Specify a directory containing C files to process. A trailing / is permitted on the directory name and has no impact on the result. By default, the include path will be set to the "include" subdirectory of this directory. A different include path can be specified using the option -I. -dir only considers the rightmost directory in the argument list. This behavior is convenient for creating a script that always works on a single directory, but allows the user of the script to override the provided directory with another one. Spatch collects the files in the directory using find and does not follow symbolic links.
  - **-kbuild\_info**  $\langle$  **file** $\rangle$  The specified file contains information about which sets of files should be considered in parallel.
  - -disable\_worth\_trying\_opt Normally, a C file is only processed if it contains some keywords that have been determined to be essential for the semantic patch to match somewhere in the file. This option disables this optimization and tries the semantic patch on all files.

- -test (file) A shortcut for running Coccinelle on the semantic patch "file.cocci" and the C file "file.c".
- -testall A shortcut for running Coccinelle on all files in a subdirectory tests such that there are all of a .cocci file, a .c file, and a .res file, where the .res contains the expected result.
- -test\_okfailed, -test\_regression\_okfailed Other options for keeping track of tests that have succeeded and failed.
- -compare\_with\_expected Compare the result of applying Coccinelle to file.c to the file file.res representing the expected result.
- **-expected\_score\_file**  $\langle$  **file** $\rangle$  which score file to compare with in the testall run

## 3.3 Parsing C files

- ♦ -show\_c Show the C code that is being processed.
- -parse\_error\_msg Show parsing errors in the C file.
- ♦ -verbose\_parsing Show parsing errors in the C file, as well as information about attempts to accommodate such errors. This implicitly sets -parse\_error\_msg.
- ♦ -type\_error\_msg Show information about where the C type checker was not able to determine the type of an expression.
- → -int\_bits ⟨n⟩, -long\_bits ⟨n⟩ Provide integer size information. n is the number of bits in an unsigned integer or unsigned long, respectively. If only the option -int\_bits is used, unsigned longs will be assumed to have twice as many bits as unsigned integers. If only the option -long\_bits is used, unsigned ints will be assumed to have half as many bits as unsigned integers. This information is only used in determining the types of integer constants, according to the ANSI C standard (C89). If neither is provided, the type of an integer constant is determined by the sequence of "u" and "l" annotations following the constant. If there is none, the constant is assumed to be a signed integer. If there is only "u", the constant is assumed to be an unsigned integer, etc.
- -no\_loops Drop back edges for loops. This may make a semantic patch/match run faster, at the cost of not finding matches that wrap around loops.
  - -use\_cache Use preparsed versions of the C files that are stored in a cache.
  - -debug\_cpp, -debug\_lexer, -debug\_etdt, -debug\_typedef Various options for debugging the C parser.
  - -filter\_msg, -filter\_define\_error, -filter\_passed\_level Various options for debugging the C parser.
  - -only\_return\_is\_error\_exit In matching "..." in a semantic patch or when forall is specified, a rule must match all control-flow paths starting from a node matching the beginning of the rule. This is relaxed, however, for error handling code. Normally, error handling code is considered to be a conditional with only a then branch that ends in goto, break, continue, or return. If this option is set, then only a then branch ending in a return is considered to be error handling code. Usually a better strategy is to use when strict in the semantic patch, and then match explicitly the case where there is a conditional whose then branch ends in a return.

### Macros and other preprocessor code

- -macro\_file (file) Extra macro definitions to be taken into account when parsing the C files.
- -macro\_file\_builtins (file) Builtin macro definitions to be taken into account when parsing the C files.
- → -ifdef\_to\_if,-no\_ifdef\_to\_if The option -ifdef\_to\_if represents an #ifdef in the source code as a conditional in the control-flow graph when doing so represents valid code. -no\_ifdef\_to\_if disables this feature. -ifdef\_to\_if is the default.
- ♦ -use\_if0\_code Normally code under #if 0 is ignored. If this option is set then the code is considered, just like the code under any other #ifdef.
  - -noadd\_typedef\_root This seems to reduce the scope of a typedef declaration found in the C code.

#### Include files

- → -all\_includes, -local\_includes, -no\_includes These options control which include files mentioned in a C file are taken into account. -all\_includes indicates that all included files will be processed. -local\_includes indicates that only included files in the current directory will be processed. -no\_includes indicates that no included files will be processed. If the semantic patch contains type specifications on expression metavariables, then the default is -local\_includes. Otherwise the default is -no\_includes. At most one of these options can be specified.
- ◆ -I ⟨path⟩ This option specifies the directory in which to find non-local include files. This option should be used only once, as each use will overwrite the preceding one.
- ♦ -relax\_include\_path This option when combined with -all\_includes causes the search for local include files to consider the directory specified using -I if the included file is not found in the current directory.

# 4 Application of the semantic patch to the C code

## 4.1 Feedback at the rule level during the application of the semantic patch

- ◆ -show\_bindings Show the environments with respect to which each rule is applied and the bindings that result from each such application.
- → -show\_dependencies Show the status (matched or unmatched) of the rules on which a given rule depends.
  -show\_dependencies implicitly sets -show\_bindings, as the values of the dependencies are environment-specific.
- -show\_trying Show the name of each program element to which each rule is applied.
- → -show\_transinfo Show information about each transformation that is performed. The node numbers that are referenced are the number of the nodes in the control-flow graph, which can be seen using the option -control\_flow (the initial control-flow graph only) or the option -show\_flow (the control-flow graph before and after each rule application).
- -show\_misc Show some miscellaneous information.

- -show\_flow \( \file \), -show\_flow \( \file \):\( \function \) Show the control-flow graph before and after the application of each rule.
  - **-show\_before\_fixed\_flow** This is similar to **-show\_flow**, but shows a preliminary version of the control-flow graph.

## 4.2 Feedback at the CTL level during the application of the semantic patch

- **♦** -verbose\_engine Show a trace of the matching of atomic terms to C code.
- ♦ -verbose\_ctl\_engine Show a trace of the CTL matching process. This is unfortunately rather voluminous and not so helpful for someone who is not familiar with CTL in general and the translation of SmPL into CTL specifically. This option implicitly sets the option -show\_ctl\_text.
- ◆ -graphical\_trace Create a pdf file containing the control flow graph annotated with the various nodes matched during the CTL matching process. Unfortunately, except for the most simple examples, the output is voluminous, and so the option is not really practical for most examples. This requires dot (http://www.graphviz.org/) and pdftk.
- ♦ -gt\_without\_label The same as -graphical\_trace, but the PDF file does not contain the CTL code.
- ♦ -partial\_match Report partial matches of the semantic patch on the C file. This can be substantially slower than normal matching.
- ♦ -verbose\_match Report on when CTL matching is not applied to a function or other program unit because it does not contain some required atomic pattern. This can be viewed as a simpler, more efficient, but less informative version of -partial\_match.

## 4.3 Actions during the application of the semantic patch

- → -D rulename Run the patch considering that the virtual rule "rulename" is satisfied. Virtual rules should be declared at the beginning of the semantic patch in a comma separated list following the keyword virtual. Other rules can depend on the satisfaction or non satisfaction of these rules using the keyword depends on in the usual way.
- ◆ -D variable=value Run the patch considering that the virtual identifier metavariable "variable" is bound to "value". Any identifier metavariable can be designated as being virtual by giving it the rule name virtual. An example is in demos/vm.coci
- ♦ -allow\_inconsistent\_paths Normally, a term that is transformed should only be accessible from other terms that are matched by the semantic patch. This option removes this constraint. Doing so, is unsafe, however, because the properties that hold along the matched path might not hold at all along the unmatched path.
- ♦ -disallow\_nested\_exps In an expression that contains repeated nested subterms, e.g. of the form f(f(x)), a pattern can match a single expression in multiple ways, some nested inside others. This option causes the matching process to stop immediately at the outermost match. Thus, in the example f(f(x)), the possibility that the pattern f(E), with metavariable E, matches with E as x will not be considered.

- ♦ -no\_safe\_expressions normally, we check that an expression does not match something earlier in the disjunction. But for large disjunctions, this can result in a very big CTL formula. So this option give the user the option to say he doesn't want this feature, if that is the case.
- -pyoutput coccilib.output.Gtk, -pyoutput coccilib.output.Console This controls whether Python output is sent to Gtk or to the console. -pyoutput coccilib.output.Console is the default. The Gtk option is currently not well supported.
  - **-loop** When there is "..." in the semantic patch, the CTL operator AU is used if the current function does not contain a loop, and AW may be used if it does. This option causes AW always to be used.
  - -steps (int) This limits the number of steps performed by the CTL engine to the specified number. This option is unsafe as it might cause a rule to fail due to running out of steps rather than due to not matching.
  - **-bench**  $\langle int \rangle$  This collects various information about the operations performed during the CTL matching process.
  - -popl, -popl\_mark\_all, -popl\_keep\_all\_wits These options use a simplified version of the SmPL language. -popl\_mark\_all and -popl\_keep\_all\_wits implicitly set -popl.

## 5 Generation of the result

Normally, the only output is a diff printed to standard output.

- ◆ -keep\_comments Don't remove comments adjacent to removed code.
- → -linux\_spacing, -smpl\_spacing Control the spacing within the code added by the semantic patch. The option -linux\_spacing causes spatch to follow the conventions of Linux, regardless of the spacing in the semantic patch. This is the default. The option -smpl\_spacing causes spatch to follow the spacing given in the semantic patch, within individual lines.
- **♦** -o ⟨file⟩ The output file.
- **♦** -inplace Modify the input file.
- **♦** -outplace Store modifications in a .cocci\_res file.
- ♦ -no\_show\_diff Normally, a diff between the original and transformed code is printed on the standard output. This option causes this not to be done.
- ♦ -U Set number of diff context lines.
- → -patch (path) The prefix of the pathname of the directory or file name that should dropped from the diff line in the generated patch. This is useful if you want to apply a patch only to a subdirectory of a source code tree but want to create a patch that can be applied at the root of the source code tree. An example could be spatch -sp\_file foo.cocci -dir /var/linuxes/linux-next/drivers -patch /var/linuxes/linux-next. A trailing / is permitted on the directory name and has no impact on the result.

- ◆ -save\_tmp\_files Coccinelle creates some temporary files in /tmp that it deletes after use. This option causes these files to be saved.
  - **-debug\_unparsing** Show some debugging information about the generation of the transformed code. This has the side-effect of deleting the transformed code.

## 6 Other options

### 6.1 Version information

- -version The version of Coccinelle. No other options are allowed.
- ◆ -date The date of the current version of Coccinelle. No other options are allowed.

## 6.2 Help

- -h, -shorthelp The most useful commands.
- ◆ -help, -help, -longhelp A complete listing of the available commands.

### 6.3 Controlling the execution of Coccinelle

- -timeout (int) The maximum time in seconds for processing a single file.
- **♦** -max ⟨int⟩ This option informs Coccinelle of the number of instances of Coccinelle that will be run concurrently. This option requires -index. It is usually used with -dir.
- **♦** -index ⟨int⟩ This option informs Coccinelle of which of the concurrent instances is the current one. This option requires -max.
- igoplus -mod\_distrib When multiple instances of Coccinelle are run in parallel, normally the first instance processes the first n files, the second instance the second n files, etc. With this option, the files are distributed among the instances in a round-robin fashion.
  - -debugger Option for running Coccinelle from within the OCaml debugger.
  - -profile Gather timing information about the main Coccinelle functions.
  - -disable\_once Print various warning messages every time some condition occurs, rather than only once.

#### 6.4 Miscellaneous

♦ -quiet Suppress most output. This is the default.

-pad, -hrule  $\langle dir \rangle$ , -xxx, -l1
